FOR THE COMMANDER

RABERT A. McCLATCHEY, Director Atmospheric Sciences Division

This report has been reviewed by the ESD Public Affairs Office (PA) and is releasable to the National Technical Information Service (NTIS).

Qualified requestors may obtain additional copies from the Defense Technical Information Center. All others should apply to the National Technical Information Service.

If your address has changed, or if you wish to be removed from the mailing list, or if the addressee is no longer employed by your organization, please notify AFGL/DAA/LYC, Hanscom AFB, MA 01731-5000. This will assist us in maintaining a current mailing list.

Do not return copies of this report unless contractual obligations or notices on a specific document requires that it be returned.

### 1.0 TECHNICAL BACKGROUND

Following the development of radar in the mid-1940's, investigators began to notice a pattern of enhanced radar reflectivity near the melting level in some precipitating clouds. This phenomenon was labeled the "bright band" and was the subject of several earlier theoretical and observational investigations (for example, see Ryde, 1946; Cunningham, 1947; Austin and Bemis, 1950; Marshall and Gunn, 1952; Wexler, 1955; Lhermitte and Atlas, 1963). Battan (1973) summarizes these earlier works which concluded that the bright band occurred in conjunction with the melting of snowflakes or an ice crystal aggregation process (as opposed to the accretional process which forms graupel and hail in convective clouds). However, these inferences were drawn without the benefit of in-situ observations and therefore did not explain the physics of the process.

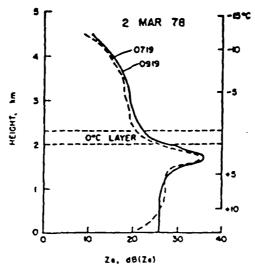

The advent of PMS two-dimensional imaging probes (Knollenberg, 1976) facilitated the determination of <a href="in-situ">in-situ</a> hydrometer size distribution from airborne measurements (Gordon and Marwitz, 1984). This has led to the recent evaluation of the physical processes associated with bright bands using observations from aircraft by Stewart <a href="etc.gl">etc.gl</a> (1984). This work presented a comprehensive picture of thermodynamic and microphysical processes associated with the bright bands near the Sierra Nevada mountains in California. This report also presents some <a href="in-situ">in-situ</a> airborne observations with concurrent radar observations to help identify the physical processes associated with the melting layer.

### 1.1 Physical Processes in the Melting Layer.

Radar observations typically show an enhanced reflectivity (in bright band) on the order of 10-15 dBZ increase in reflectivity, located about 300 m below the 0°C isothermal layer. Several physical factors have been proposed which could theoretically increase radar reflectivity in the bright band (see Battan, 1973 and Cohen and Sweeney, 1983 for a review); however, an evaluation of the most recent data strongly suggests that a shift in particle size distribution toward larger sizes is the most probable explanation. Since the aggregation efficiency is directly related to temperature until melting occurs, and since recent observations by Stewart et al. (1984) show a strong correlation between aggregation and the bright band effect, there is strong evidence that the bright band is associated with aggregation. Figure 1.1 is a reproduction from Stewart et al. (1984) showing the correlation between ice particle size (measured by the PMS 2-D probes) and radar reflectivity. also point out that another factor which may support the aggregation process is an ice multiplication process active at -5°C (Hallett and Mossop, 1974). As shown in Figure 1.1, there exists a threefold increase in ice crystals (needle shaped) near -5°C. These needles may form aggregates or combine with existing dendritic crystals to form large lacy aggregates. large aggregates would presumably tend to clump together near the

Simultaneous profiles of reflectivity factor Z and root-mean-square particlefall speed in light (1 mm/hr), steady precipitation with a bright band. From Lhermitte and Atlas (1963).

Vertical profile of radar reflectivity, and the cross section of the King Air flight track from 0711 PST (takeoff) to 0725 PST on 2 March 1978. The radar data were computed from a 7.5° elevation scan of the CP-3 radar at 0719 PST and from a 12.5° elevation angle scan at 0919 PST. (From Stewart et al. (1984)

Figure 1.1 Examples of Bright Band Radar Reflectivity

melting layer and melt into large drops which enhance radar reflectivity.

The effect of water-coated ice particles on radar reflectivity has been studied, and, according to Ekpenyong and Srivastava, (1970), when one-third of the original volume of ice has melted into a water film surrounding the ice, the index of refraction will have changed from ice to that of water. Cohen and Sweeney estimate that this would result in a 33 dBZ increase in radar reflectivity (much larger than the observed effect). However, Knight (1979) found that a circular shell of water only forms in the advanced stage of melting. Consequently, the possibility exists that an effective increase in hydrometeor diameter resulting from a less dense ice center could enhance radar reflectivity. This process is difficult to ascertain from aircraft observations.

Another feature associated with bright bands is the relative decrease in radar reflectivity below the melting layer. The increase in fall speed of the rain drops below the melting layer (see Figure 1.2) will create an effective decrease in number concentration. Lhermitte and Atlas (1963) found that this accounted for about one-third of the observed decrease in reflectivity below the melting layer (about 8 dBZ) was accounted for by the increase in fall velocity (4 dBZ) and the change in shape factor to spherical (about 3 dBZ). Stewart et. al. also concluded that raindrop collisional breakup below the melting layer was significant and tended to shift the drop size spectra toward a Marshall-Palmer distribution with the increasing temperature. The decrease in observed radar reflectivity was in agreement with the shift in the size spectra toward smaller diameters.

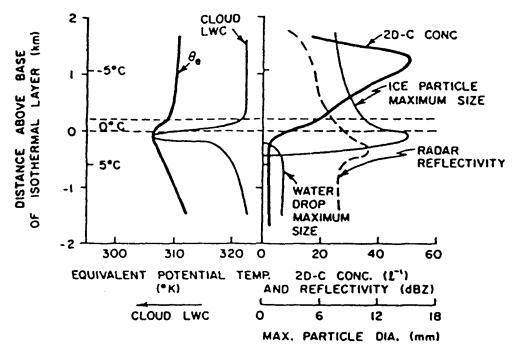

The aforementioned observations discussed in the literature suggest that several physical processes which affect the melting level (and the ensuing bright band) are complex and interactive. It is also apparent that the physical processes which affect the melting layer have their origins at colder temperatures (i.e., ice multiplication and aggregation) and extend well below the bright band (i.e., increased terminal velocity and collision breakup). In the present work we discuss airborne measurements in the melting layer in terms of this chain of events.

### 1.2 Overview of Airborne Measurement Systems.

SAIVERSTRAND SECTION OF SECRETARY BESCHOOLS SECRETARY SECRETARY DESCRIPTION OF SECRETARY

For this study of the melting layer CIC provided the PMS twin engine turbo-charged Beech Baron (Figure 1.3) which is fully de-iced and has a good performance capability at the altitudes covered in this project. (See Section 1.3 for the Beech Baron aircraft specifications.)

The Baron carries, in standard research configuration, a full compliment of PMS partic'e sizing and imaging probes, a gust boom and the conventional state parameter sensors. A multiple

Schematic profile illustrating significant trends of various microphysical and state parameters through a typical melting layer as deduced by synthesizing the observations of all the case studies.

Figure 1.2 Profile Illustrating Trends of Microphysical and State Parameters at the Melting Layer (from Stewart et al., 1984).

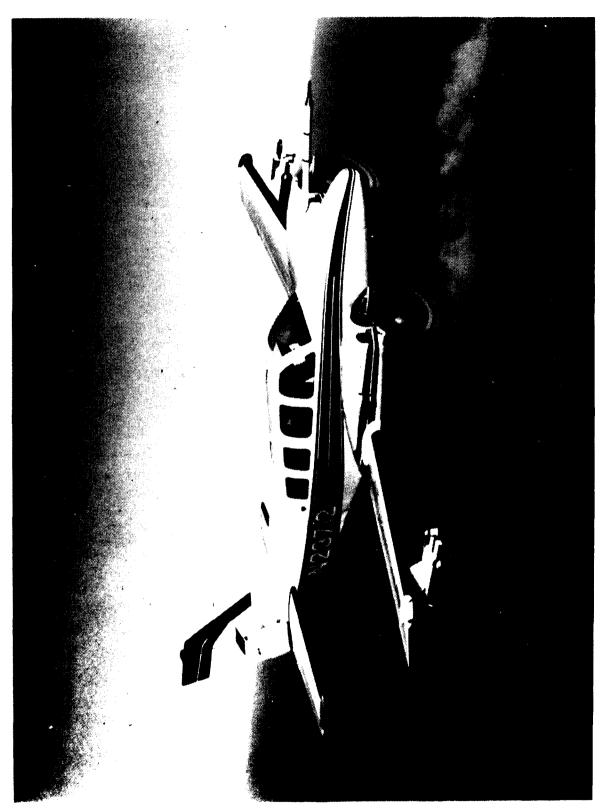

Figure 1.3 Beechcraft Baron research aircraft used in the AFGL Melting Layer Studies.

DME position keeping system was installed which cycles through six VORTAC stations every six seconds, and provides position accuracy of better than 0.5 km in straight flight. A forward looking Ka band radar was installed in the nose of the Beechcraft Baron (in place of the standard radar). The return video was processed by fifteen range gates, displayed in real time on the cockpit display, and recorded on magnetic tape.

The data were recorded on computer-compatible nine track magnetic tape. A CRT display presented real-time data in engineering units to the scientist in the cockpit. A hard-copy printer output of the data was also available to the scientist in flight.

The post flight data processing was done on the CIC IBM-XT and the AFGL Vax systems. The AFGL system also benefitted from the use of several man-years of data analysis software developed by CIC and the University of Wyoming during the HIPLEX project (see Appendix B). Examples of the computer products are given in Section 3.0.

### 1.3 Performance of Beech Baron Aircraft

The performance characteristics of the Beech Baron research aircraft are shown in Table 1.1.

### Table 1.1

### TURBOCHARGED BEECHCRAFT BARON MODEL 58-TC, N23712

Power, each engine	310 hp
Maximum speed	235 kts.
Fuel capacity	175 gal
Service ceiling	25,000 ft
Single engine service ceiling	13,000 ft
Climb at gross wt	1500 ft/min
Maximum endurance	5 hrs
Maximum range	900 nm
Take-off distance	2400 ft
Landing distance	2500 ft
Gross weight	6100
Empty weight	4570
Seating (Restricted Catagory)	3 crew
Length	30 ft
Wing span	38 ft

### 1.4 Cloud Physics Instrumentation.

### 1.4.1 Particle Spectrometers.

The PMS research aircraft is equipped with a Forward Scattering Spectrometer Probe (FSSP), Optical Array Two Dimensional Cloud Particle Imaging Probe (2D-C) and a Two Dimensional Precipitation Imaging Probe (2D-P). The FSSP sizes and counts particles from 0.5 to 45 microns, the 2D-C sizes and counts particles from 25-200 microns and the 2D-P operates in the range from 200-6400 microns. Figure 1.3 shows the PMS particle spectrometer probes mounted on the wing tips of the Baron. CIC has previously developed copious software to process PMS spectrometer probe data; samples of computer products are shown in Section 3.

The PMS 2D-C probe is equipped with a depolarization option which helps to discriminate ice and water particles. The depolarization feature works on the principle that a birefringent substance such as ice will change the polarization vector of incident polarized light, whereas water drops will not significantly affect the polarization vector. Although the discrimination is not absolute in all cases (i.e., large asymmetrical drops can cause a change in the polarization vector) the signal is a good indication of the relative phase of hydrometeors (Lawson and Stewart, 1983).

# 1.4.2 State Parameter and Air Motion Sensing Instrumentation.

Table 1.2 lists the performance characteristics of the research instrumentation used by CIC. All sensors and systems were calibrated at the CIC/PMS facility prior to the field season. A tower fly-by was conducted at the instrumented BAO/NOAA tower located 10 miles east of the Boulder Airport to verify the dynamic calibration of pressure, temperature and dew point temperature prior to the field season.

### 1.5 Ka Band Weather Radar.

CIC provided a Westinghouse AN/APD-7 Ka band radar for use on this project (see Table 1.3 for radar characteristics). The existing X-Band radar was removed and the APD-7 radar was located in its place.

Radar signal processing was accomplished using an integrating sample and hold circuit (referred to as a video

integrating processor or VIP) which had previously been used by CIC on several of its ground based radar systems.

The radar transmitter generated a 0.1 micro second pulse and the return video was integrated and recorded every 1.0 seconds. A series of range gates were recorded with the first gate set at 600m ahead of the aircraft, and subsequent gates spaced as shown in Table 1.3.

### 1.6 Navigation Systems.

### 1.6.1 Multi-DME Position System.

CIC developed a multi-DME position system for use in positioning the research aircraft. The system recorded distance data from up to six different ground-based VORTAC stations at a rate of one station per second. The KDM-7000 DME used in this system has a resolution of 20 m. and the system accuracy is on the order of 200 m. when four or more stations are received (Lawson et. al., 1980). An additional advantage was that there is no drift with time (as in INS positioning systems) since the absolute data are refreshed every six seconds. The area around Hanscom AFB is densely populated with VORTAC stations as shown in Pigure 1.4. At normal flight levels around Hanscom AFB DME signal reception was adaquate and gave good positions for this melting layer project.

### 1.6.2 VOR/DME.

The CIC data system routinely recorded aircraft VOR and DME data on the research data system, as well as multi-DME. Position from VOR/DME is only accurate to about 1 km., but the data are very reliable and provided useful redundancy (the multi-DME system failed on some days).

### 1.7 Post Season Data Processing.

CIC copied all the raw data tapes onto 9-track 1600 bpi computer compatible magnetic tape and delivered these tapes, along with all data reduction programs (written in Fortran and formatted in ASC II on 9-track computer compatible magnetic tape) to AFGL personnel. All notes recorded by the on-board scientist were delivered to AFGL. CIC and OPHIR personnel then continued to work with AFGL personnel to develop analysis software and techniques to elucidate the microphysical and thermodynamic processes operating within and near the melting layer.

### 1.8 AFGL M-meter.

The AFGL M-meter estimates the integrated mass of hydrometeors which are impacted on a rapidly spinning disk by measuring the change in angular momentum of the disk. The M meter was installed on the starboard wing pylon which also carries the PMS FSSP probe (see Figure 1.3). Proper wiring was

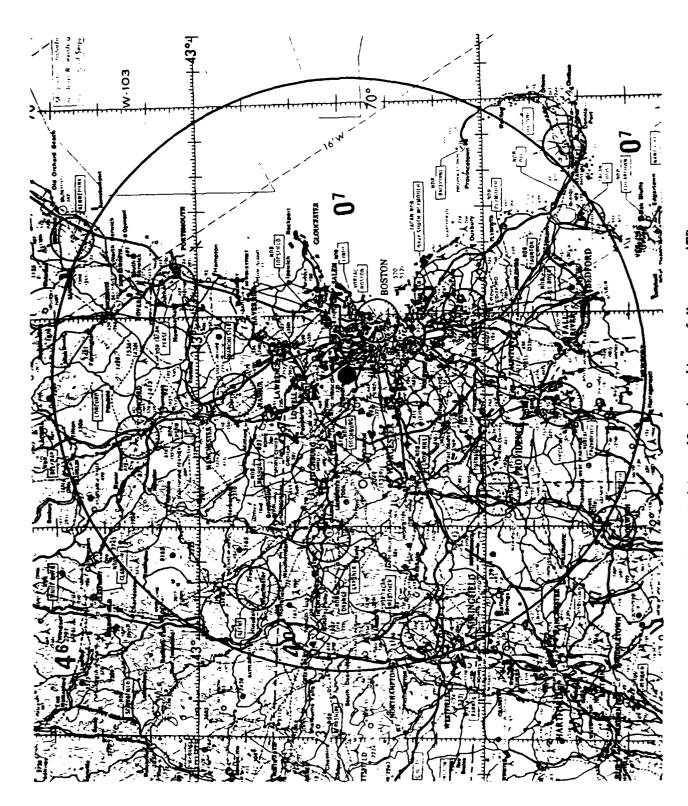

Figure 1.4 VORTAC Stations within a 60 nmi radius of Hanscom AFB

already available to provide electrical power and to transfer the output signal directly to the PMS Data Acquisition System (DAS).

In-flight data were available on the cockpit CRT and the real-time printer. Thus, field evaluation of the unit was conducted on a flight-by-flight basis. The primary evaluation tool was comparison of the unit output with the PMS probes, however, lack of sufficient funding preempted any detailed analysis, and inquiries on this matter should be directed to Mr. Vern Plank of the AFGL.

TARGET CONTRACTOR SECRET SESSENT SESSE

### 2.0 FIELD OPERATIONS.

### 2.1 Period of Operations.

The aircraft operated from Hanscom Field from March 17, 1986 through May 22, 1986. The aircraft was stationed at the Piper fixed base operator at Hanscom Field.

### 2.2 Air Traffic Control Procedures.

Prior to the field program CIC's pilot visited the Boston ATC center in order to explain the proposed flight operations and to obtain their cooperation in filing flight plans. The aircraft was given a code name "Cloudy I." This code name helped to identify to the FAA controllers the special aspects of this flight operation.

### 2.3 Flight Operations.

Table 2.1 is the flight summary for this project. A total of 53.5 hours were flown on test flights, ferry to and from Hanscom and on observational flights.

A standard flight profile was established for the purpose of measuring the chain of events of the cloud physical passes as they occur above, through, and below the 0  $^{\circ}$ C level. Figure 2.1 shows an example of the profile chosen. After take-off the aircraft ascended to the -4  $^{\circ}$ C level. Then, in a series of passes, the aircraft would alter its altitude to pass through the vertical depth of the melting layer.

The horizontal tracks were designed such that the center of the vertical profile would occur over Sudbury where ground-based precipitation sensors and weather radars were stationed. However, due to air traffic control problems, not all profiles could be accomplished as planned.

### 2.4 Data Tapes.

All data tapes were copied and given to the Air Force personnel within 48 hours after each flight. The observer flight notes were also provided. Copies of these notes were also retained by CIC for further post-field analysis.

### 3.0 SOFTWARE FOR DATA REDUCTION AND ANALYSIS.

### 3.1 Background.

The instrumented aircraft collected data on magnetic tape which was transcribed to hardcopy computer products after each flight. These computer products provided the AFGL with a quick-turnaround evaluation of the mission performance (for example see Figure 3.1).

During a meeting on 13 May 1986 with AFGL and CIC personnel, it was agreed that CIC personnel would pursue the analysis of data after the close of the field season (an extension of the field season by the AFGL due to lack of suitable weather reduced the original estimate of funds available for data analysis). AGFL personnel recommended that CIC develop software to produce the following computer products:

- 1. Plan view of aircraft position as a function of time.
- Integrated total water content and equivalent radar reflectivity including artifact rejection from the PMS FSSP, 2DC and 2DP particle imaging data.
- 3. Time series plots of the airborne Ka-band radar reflectivity data which have been time-correlated for distance from the aircraft.
- 4. Spectral analysis of correlation between the airborne Ka-band radar data with particle image data.

It was further agreed that CIC would use these software tools to produce plan-view and vertical cross-section analyses of the melting layer data identifying the location and type of hydrometeors, the depth of the melting layer and the precipitation processes which were active. These <u>in-situ</u> data were intended to be correlated with remote-sensing data from ground-based radars and satellite beacons.

### 3.2 Computer Software Products.

### 3.2.1 PMS 2D Images.

Figure 3.2 is an example of PMS 2DC and 2DP image data collected on 27 March 1986. The images are underscored by lines of meteorological data collected by the aircraft at the same time.

### 3.2.2 Aircraft Track.

Figure 3.3 is an example of a plot of aircraft track from the multiple DME system as a function of time. Since the aircraft flew repeated legs over the same location on the ground, it is necessary to separate a mission into several time periods for the sake of clarity. Appendix A contains the flight tracks

### 3.2.3 PMS Hydrometeor & Ka-band Radar Data Comparison.

Figures 3.4 - 3.5 are examples of the correlation between the reflectivities from the airborne Ka-band radar and the equivalent radar reflectivity integrated from the PMS The hydrometeor data are corrected for hydrometeor spectra. artifact rejection (artifacts created by particles colliding with the probe tips, cloud water streaking across the mirrors, etc.) using the algorithm reported by Cooper (1978). The airborne Kaband radar sees hydrometeors well ahead of the aircraft (from 0.6 to 36 km), and these data are adjusted in time using the recorded true airspeed to correspond with the PMS particle imaging data. The data in Figures 3.4 & 3.5 show a casual correlation between equivalent reflectivity from the integrated hydrometeor spectra and the first range bin of the airborne data, but we fail to see any correlation extending beyond the first range gate. We feel that this is due to the very light precipitation (maximum of 2 mm diameter drops), and that the reflected radar signal was lost in the noise past the first range gate.

Figure 3.6 shows an ensemble plot of equivalent radar reflectivity from the 2DP probe versus the first range gate of the airborne radar, and indicates that the data contain a large degree of variance.

### 3.2.4 Spectral Analysis.

The correlation between two variables can be examined in the frequency domain using FFT analysis techniques. Figures 3.7a, b and c show the correlation between the first range gate from the airborne Ka-band radar reflectivity (adjusted in time) and the equivalent reflectivity from the integrated spectra seen by the 2DP probe. The coherence plot shows significant correlation out to about 0.05 Hz, which corresponds to 1.6 km at a true airspeed of 80 m/s. This is some indication of the degree of stationarity in the precipitation field during this mission.

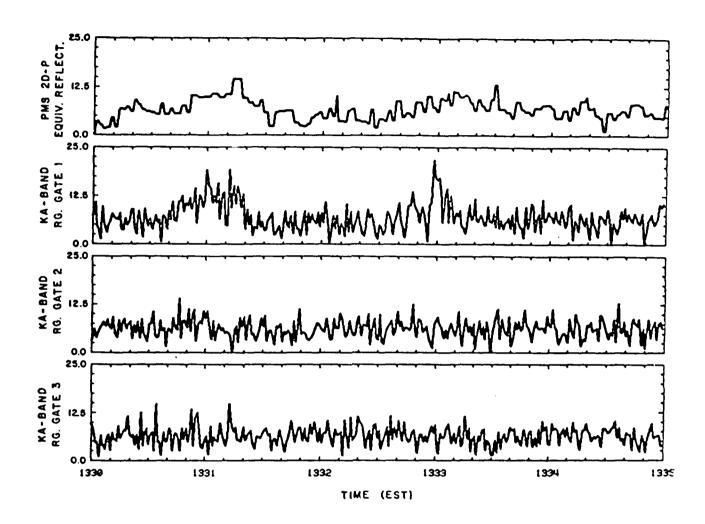

Figure 3.4 Example of time series data showing equivalent reflectivity from PMS 2D-P image data (top) and reflectivities from the first three range gates of the airborne Ka-band radar which have been shifted in time to correspond with the position in space of the image data collected on 5/12/86.

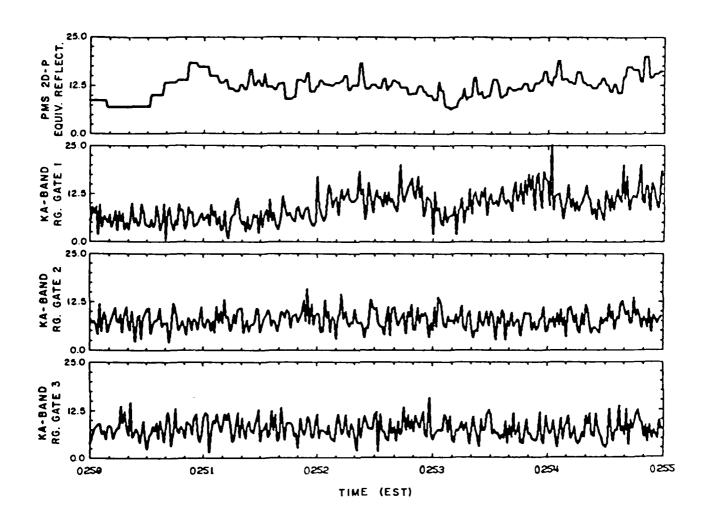

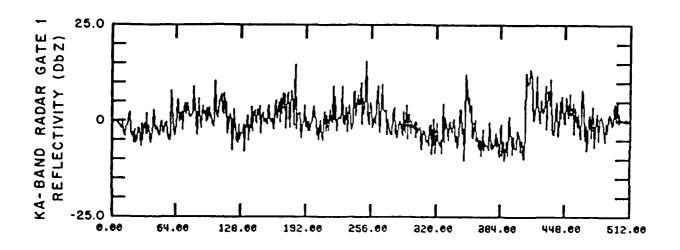

Figure 3.5 As in Figure 3.4 except for data collected on 5/17/86.

### 4.0 CASE STUDIES.

### 4.1 Overview.

As pointed out in Section 1.0, understanding the physical chain of events leading to the formation of precipitation is the major concern in describing characteristics of the melting layer. During the field observational period the Baron research aircraft collected data at various levels above, below and near the  $^{0}$ C level. The purpose of this section is to examine the images as seen by the PMS 2D probes and correlate these observations with the formation of precipitation.

Vertical cross sections of the 2DP data have been analyzed and for each leg of the flight track the 2DP images have been studied to determine the occurrence of various types of solid precipitation and to estimate the elevation at which these hydrometeors melted. Since funding for analyses of these cases is limited, we have chosen to present a brief description of the five cases selected, with a more detailed analysis of a portion of the 27 April case. This case provided the best example of a steady state episode which allowed us to draw some generalizations. The other cases generally support the major findings of the 27 April study, and a summary of these results is presented in Section 4-6

### 4.2 Case Study I (4 7 86)

On this day the aircraft first climbed to about 3000 m and made a NE pass over the area. The temperature at this level was 3.3°C. Along this track the PMS 2DP probe showed a mixture of graupel and needles (mostly in mutually exclusive pockets of one or the other). Near the end of this leg there were graupel particles and sign. Comming. There were moderate sized 2DC images also showing evidence of riming.

Leg two was the reverse pass (westerly) at the same altitude and showed similar images. There were a few aggregates on this pass.

The aircraft then descended to shout 1500 m where the temperature was 4.0 $^{\circ}$ C. All along this leg the 2DP showed a uniform pattern of rain images. Next the aircraft climbed to about 1650 m where the temperature was 3.5 $^{\circ}$ C. Along this leg there were mostly 1.2 mm raindrops

Image data for the remainder of the flight are not available

## 4.3 Case Study II (4 26 86)

The first two legs of this flight were made at about 2000 m where the temperature was 2.4 $^{\circ}$ C. Image data for this portion of the flight were not available. The three was made in a southwesterly direction at 1900  $\tau$  .3.6 $^{\circ}$ C). The images show mostly raindrops with an occasional numbered aggregate observed.

especially near the western end of the track.

The aircraft next climbed to  $2150~\mathrm{m}$  ( $2.2^{0}\mathrm{C}$ ) and started leg four in a NE direction. On this leg there were large unmelted aggregates mixed with small raindrops. Some of the aggregates were quite large. The aircraft then ascended to about 2200 m (1.4°C) and started leg five. Again on this leg there were large unmelted aggregates mixed with small raindrops.

Leg six was flown at 2300 m where the temperature was just about 0°C. The images were a mixture of medium-sized aggregates and graupel particles, which did not co-exist but appeared to occur in patches, a re-occurring theme found in the data. There was a large variation in particle concentration along this leg. Leg seven was flown at 2400 m (0.4°C and had images very similar to leg six (mixture of aggregates and graupel). Leg eight was a reciprocal leg of seven and showed the same types of images as did leg nine.

Leg ten started at 2500 m, then the aircraft ascended to about 2700 m (-1.2 $^{\circ}$ C). The images were a mixture of large aggregates and small graupel. The 2DC malfunctioned and the image data were unusable on this leg. Next the aircraft ascended to 2800 m (-1.8 $^{\circ}$ C) and made legs eleven and twelve at this altitude. The images on these legs were mostly graupel particles with a few large aggregates, and some needles.

At 0342 EST the aircraft descended to about 1800 m (2.9 $^{\circ}$ C and conducted leg 13. On this leg there were mostly 1-3 mm raindrops with a few large, unmelted aggregates.

THE PROPERTY OF THE PROPERTY O

## 4.4 Case Study III (4-27-86).

This case has the most extensive set of cloud physics data with 25 legs flown in three separate vertical profiles. Table 4.1 describes the first 11 legs on this flight. The aircraft ascended from 1800 to 2700 m while making transects from Hanscom AFB to Sudbury. The principle precipitation mechanism during this profile seemed to be an aggregation process. Large aggregates (2.5 mm) were observed to form just above the 0°C level and melted forming 1.2 mm rain after descending about 800 m. Occasional large melted aggregates were observed along with the rain drops. There were few graupel particles observed during this profile, and the accretional growth of ice into graupel particles did not appear to be a significant precipitation mechanism. This vertical profile is notably different from that observed later (0120 0214) which showed discrete pockets of either graupel or aggregates.

TABLE 4.1. Description of Hydrometeors Observed by the PMS Probes on the Baron Aircraft During the First Vertical Profile on 27 April 1986.

Leg	Time(EST)	Altitude(m)	Image Characteristics
1	0014-0019	1800 (2.0°C)	mostly rain, few large unmelted aggregates
2	0019-0024	1800 (2.0°C)	same as above
3	0025-0028	1800 (2.0°C)	same as above
4	0028-0032	2135 (0.3°C)	mostly rain, frequent large aggregates
5	0033-0038	2135(0.3°C)	same as above
6	0038-0048	2275 (0.4°C)	pockets of large aggregates, small stellars, small drops
7	0048-0053	2275 (0.4°C)	aggregates, ice particles
8	0055-0100	2431(-0.6°C)	large aggregates, few small rimed ice or graupel embryos
9	0101-0106	2431 (-0.6°C)	mixture aggregates, graupel embryos, stellar ice
10	0108-0113	2600 (-1.3°C)	many small aggregates made of needles, ice particles
11	0114-0119	2586 (-1.2°C)	few large aggregates, mostly small ice, some graupel embryos.

Table 4.2 lists the characteristics of the next eleven legs. This profile characterizes the pattern which we have seen in several other portions of the data, in that graupel particles and aggregates appear to exist in separate pockets across the cross section. The mechanisms responsible for the generation of these inhomogeneous regions are beyond the scope of this analysis (the aircraft did not ascend above -3 °C, where the formation of the graupel and ice particles originated).

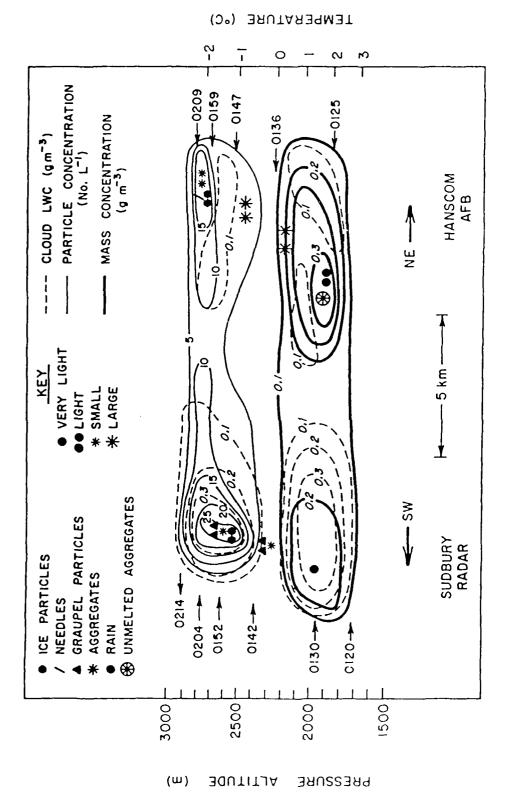

Figure 4.1 is an analysis of the vertical cross section of the data from 0120 - 0214, which suggests that there were two distinct regions of hydrometeor types. In the southwestern region (near Sudbury), relatively high concentrations (up to 30  $L^{-1}$  of ice and graupel particles were observed above the melting layer, while over the northeastern area (near Hanscom AFB), smaller concentrations of ice particles and aggregates were found above the O<sup>°</sup>C level. Examples of the images from these two regions are shown in Figure 4.2. The graupel particles co-existed with a significant region of supercooled liquid water, while the aggregates did not. This regime seemed to persist in a spatial relationship commensurate with the shear of the mean wind as the aircraft ascended, and therefore appears to be a quasi steadystate feature. This is substantiated by the rapid spiral descent from 2700 - 1800 m at 2115 which showed the evolution of graupel to small rain. Below the melting layer, the 2DP images suggest that the graupel melted into fairly uniform, small (1 mm) raindrops at a level very close to 0°C. On the other hand, the aggregates did not melt uniformly and some partially melted aggregates are seen down to +3°C, where there is a larger variance in the precipitation spectrum and several larger (1-3 mm) raindrops are observed. Examples of images from these two regions below the melting layer are also shown in Figure 4.2. thus appears that the aggregation process may have been more efficient in utilizing the available supercooled cloud water, generating larger particles which took longer to melt and subsequently produced larger raindrops. This is contrary to observations in summertime cumuli (Cooper and Lawson, 1984) and is discussed further in Section 4.6.

	0352-descent		unmelted aggregate to 4.1°C

# 4.6 Summary of Case Studies.

Figure 4.3 shows a summary of the results of the case studies. The characteristics of the images are graphically depicted as a function of temperature for each of the vertical profiles obtained, and a typical cloud liquid water content (1 - 30 micron droplet diameter) is shown. This figure clearly shows a systematic sequence of events as the cloud particles pass through the melting layers. Those events are as follows:

A. At temperatures -2<sup>O</sup>C and colder there is usually a mixture of graupel embryos (or rimed ice particles of about 0.3-0.5 mm), ice particles and small aggregates. The graupel embryos are often associated with pockets of liquid water content of a few tenths of a gram per cubic meter. These pockets are usually distinct from pockets of ice particles and small aggregates where the liquid water has been depleted. The spatial dimension of these pockets is on the order of 10 km.

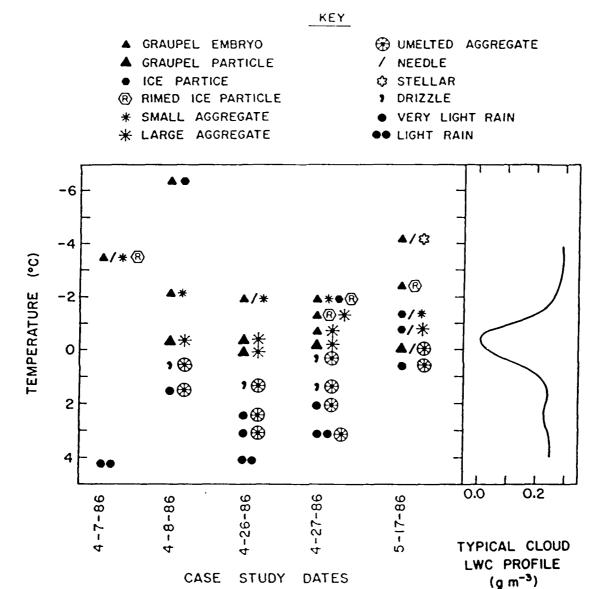

Figure 4.3 Summary of data from five case studies showing vertical profile of cloud liquid water content and evolution of hydrometeors.

2010 POSTOSIO 2000 SISSIOO PARAGOSIS

- B. Ice and small aggregates form large aggregates beginning at about -2°C. This process proceeds very rapidly with large aggregates forming near the 0°C level. When present, pockets of graupel embryos and ice grow (slowly due to the low LWC) via a wet accretional process to 1 mm graupel.
- C. Near 0°C there is a mixture of large aggregates and sometimes graupel particles, usually in discrete pockets of ~10 km across. Aggregation appears to continue through this layer while the graupel particles start to melt.
- D. At about 0.3 °C small (1-2 mm) melting aggregates and large (2-5 mm) unmelted aggregates are observed. When present, melting small (1-2 mm) graupel particles and 1 mm rain drops are observed in pockets which are usually separate from the aggregates.
- E. At +2° to +4°C large (2-5 mm) unmelted aggregates are mixed with smaller (1 mm) raindrops; any graupel particles all appear to have melted into 1 mm rain.

The primary precipitation mechanism appears to be through an aggregation process, starting with 0.2 - 0.5 mm ice particles (often needles) near -3°C and small aggregates, and leading to the formation of large (2-5 mm) aggregates near the 0°C level. These aggregates melt to form 1 2 mm rain with occasional large (2-5 mm) unmelted aggregates falling to 800 m below 0°C. Sometimes, a very different precipitation process is observed which starts with graupel embryos (~0.5 mm rimed ice particles) at -3°C, and proceeding through an accretional process which leads to the formation of small (1 mm) rain. The aggregation process appears to be more efficient in the utilization of cloud liquid water, and we suspect that this is due to the long residence time of the (slowly falling) aggregates in the region above the melting layer, resulting in dry growth from vapor deposition. The graupel particles, on the other hand, have larger fall velocities and pass quickly through the region of supercooled water above the melting layer, scavenging out a small percentage of the total volume. The relative importance of the two mechanisms is the reverse of that seen in summertime convective clouds where wet accretion is the primary precipitation process, and aggregation is usually secondary (Cooper and Lawson, 1984). This is due to the much higher initial liquid water contents of convective clouds (favoring accretional growth), and the subsequent rapid depletion of cloud water via entrainment (reducing the lifetime shortens the residence time for growth via vapor deposition and subsequent aggregation).

THE STATES OF TH

It appears that the partially melted, large aggregates, may be an explanation for the increase in radar reflectivity. It is shown that these particles can exist up to 800m or so below the  $0^{\circ}C$  level. The vertical profiles observed here are similar to those seen by other investigators (see Section 1.0 and Figure 1.1), and it appears that aggregation may play an important role

in the formation of bright bands in general.

The curious part of this chain of events is how these large aggregates develop so fast just above the O°C level. The "aggregation zone" near 0°C has often been associated with rapid rates of aggregation (Rogers, 1973). Rapid aggregation rates have also been observed by Cotton et al. (1986) at much colder temperatures (-10 to -12 $^{\circ}$ C) in wintertime storms over the Park Range in Colorado. Numerical simulations by Cotton et al. (1986) suggest that the major term in the aggregation process is the scavenging of smaller ice crystals by mature (large) aggregates via a sedimentation process. Figure 4.3 shows to -4°C there are mostly single crystals and small that at -3 clumps. But at about -2°C aggregation proceeds rapidly through to the 0°C level (distance of 300-400 m) with fall velocities of about 1 m/sec. That is, the aggregation process apparently took only 5-8 minutes, and the rate of aggregation appeared to accelerate rapidly near the 0°C level, which was also coincident with the formation of larger aggregates which would be required to scavenge smaller ice particles and aggregates via sedimentation.

# 5.0 EVALUATION OF THE M-METER

We have previously submitted a preliminary analysis of the M-meter in a special technical report to the AFGL. Subsequent refinement of the data reduction procedure which includes a bearing friction factor and the effects of heating of the impacted hydrometeors was suggested by Mr. Vern Plank of AFGL, however, lack of funds has prevented this new analysis from being completed. Interested parties should contact Mr. Plank for a current interpretation of the performance of the M-meter.

# 6.0 EVALUATION OF THE KA BAND RADAR AND ATTENUATION MEASUREMENTS.

At the beginning of the project it was thought that a nose-pointing Ka band radar could be used to measure radar reflectivity at various ranges and from these sequential measurements it would be possible to deduce attenuation. However, the Ka band radar installed for this project had a higher noise level then anticipated and thus it was difficult to obtain any clearcut measurements (see section 3.0 for examples). This problem was amplified by the fact that during the project we encountered only light to moderate precipitation. The reflectivity returns were, therefore, very weak and often buried in the noise.

The narrow beam and the small pulse width led to the sampling of relatively small volumes of cloud. From the PMS particle data we know there are large variations in particle sizes over small areas, hence significant reflectivity variations would also be expected on this scale.

and along processions and second processions and a second procession from a

Another problem was that the aircraft altered its heading on frequent occasions. This meant that the narrow beam was sampling different cloud volumes compared to those subsequently penetrated. Thus from a practical viewpoint, only range gates within a few kilometers of the radar could be used to correlate to measured hydrometeors.

#### APPENDIX A

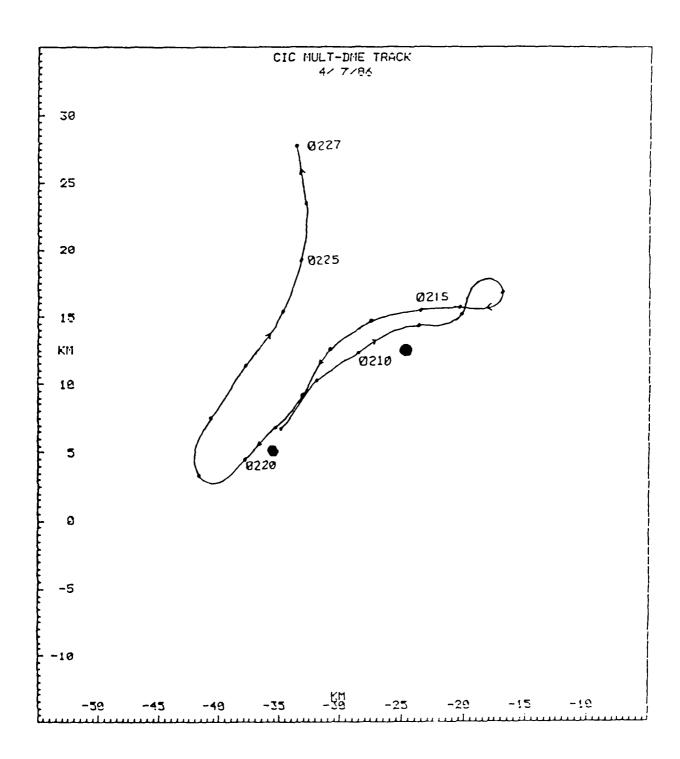

### FLIGHT TRACKS

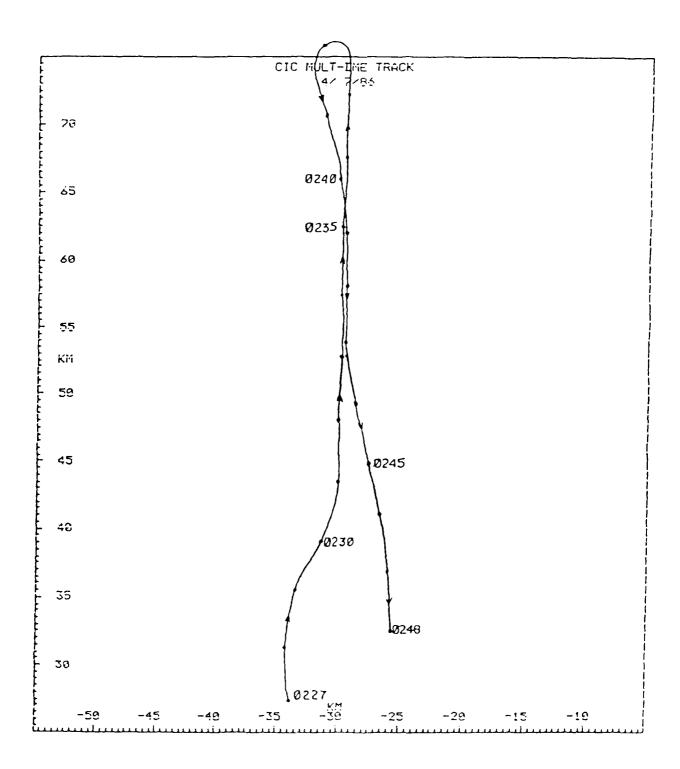

The following flight tracks were obtained using a combination of multi DME data, VOR'DME data, and dead reckoning (integrated heading and true airspeed). The accuracy of the multi-DME system is about 0.2 km in straight flight and 0.5 km in On 4-26 and 4-27 86, the multi DME was inoperative and the position is plotted using only VOR DME and dead reckoning. The accuracy of the position is degraded to about 1 km in straight flight and 2-3 km in turns. During tape changes when there are no position data the estimated track is shown in dashed lines. On 4-7-86, when the aircraft proceeded north of the primary target area, the position is estimated (but shown as a solid line) due to changes in the cockpit VOR and poor reception from the multi-DME. On 4-26-86 the aircraft proceeded north of the target area in search of precipitataion, but no usable data were obtained, and thus the aircraft position from 0232-0330 EST is not plotted. The heading gyro did not slave properly after 4-8-86 and the heading shown on the 48 hr print out (from the AFGL VAX) is in error. An offset has been added to correct these headings on 4-26-86 (-135°) and 4 27 86 (-200°). The position shown for Hanscom AFB is 296.5° true and 27.6 km, and for the Sudbury radar is  $278.5^{\circ}$  true and 36.1 km. It has come to our attention that the postion that we used for the Sudbury radar may be slightly in error; if this is the case, the aircraft tracks are still valid and the Sudbury radar postiion should be adjusted on the plots.
